# Ans?. XIII.-Description of New ume Rure Fossils obtcrined by Deep Boring in the Mallee. 

Part I.-Plantae; and Rhizopoda to Brachiopoda.

By FREDERICK CHAPMAN, A.L.S., F.R.M.S., dC. (Palaeontologist to the National Museum, Melbourne).
(With Plates XVI.-XIX).
[Read 10th July, 1913].

## Introductory Note.

In this and the two succeeding parts are embodied the palaeontological results of a somewhat exhanstive study of the material brought up by horings in the Mallee near Ouyen, numbered 1-11. The actual boring was carried ont between August, 1908, and August, 1909. The borings are all in the County of Weeah, and commence at about six miles east of the Sonth Australian boundary, and fifty miles north of the 36th parallel at Pinaroo. The bores are situated at distances of two to four miles apart.

The second part of this report will comprise the mollusea, written in conjunction with Mr. C. J. Gabriel, and the third part, by myself, will comprise the groups of the Ostracorla and Fisles.

The report containing the general results will subsequently appear in the publications of the Geological Surver of Victoria.

## Plantae.

Boring fungi, indet.
In one instance, Bore 9. 315-325 fect, the remains of a boring fungus are seen in the outer, aragonitic laver of a (?) /rowinn valve. The thallus fomms stellate groups, measuring about 3 mm . across. The tubes average ahout .115 mm . in diameter. A microscope section dial not reveal any recognisable structure.

In Bore 1, 154-190 feet, the rolled shells of mollusca are freely riddled with a similar form of perforating plant, but showing less reqularity in outline.

Genus Lithothamion, Philippi, 1837, Foslie, emend. 1900.
Lithothamniox ramosissimum, Reuss sp. (Plate X VI., Figs. 1ace, 2, 3).
Nullipora ramosissima, Reuss, 1848, Haidinger's Naturw. Abhandl.. vol. ii., pt. ii.. p. 29, pl. iii., figs. 10, 11. Unger, 1857. Denkschr. K. Akad. Wiss. Wien, vol. xiv., pp. 23, 38, pl. v., figs. 18-22.

Lithothamninm ramnsissimnm, Reuss sp., Gümbel, 1871, Abhandl. k. bayer. Akad. Wiss., vol. xi., pt. i., p. 34, pl. i., figs. $1 a-d$.
Cumulipora rosenhergi, Martin, 1881. Samml. Reichsmus. Leiden, vol. i., pt. i., pp. 12-14, 64, pl. iii., figs. 6, 7.
Lithothamnium rosenberyi, Martin sp., Martin, 1881, Ibid. rol. i., pt. ii., pp. 70,79 . Ibid, 1882, vol. i., pt. iii. pp. 153, 155.
L. ramosissimum, Rss. sp. Rothpletz, 1891. Zeitschr. deutscl. geol. Gesellsch., vol. xliii., p. 320. Nishiwada, 1894. Journ. Coll. Sci. Imp. Univ. Tokyo, vol. vii., pt. iii., p. 233, pl. xxix., figs. 1-3.
L. (Cumulipora) rosenbergi, Martin, Newton and Holland, 1900, Journ. Geol. Soc. Tokyo, vol. vii., No. 81, p. 1.
L. rosenbergi, Martin. sp. Yoshiwara, 1900, Journ. Geol. Soc. Tokyo, vol. vii., No. 81, p. 22.
Lithothamnion ramosissimum. Reuss sp.. Foslie, 1900, " Revised Systematical Survey of the Melobesidae." Kongl. Norske Vidensk. Selsk. Skr. No. 5, p. 12 (No. 14).

Lithothanmium ramosissimum, Rss. sp., Newton and Holland. 1902, Journ. Coll. Sci. Imp. Univ. Tokyo, vol. xvii., Art. 6, p. 17, pl. i., fig. 8.

Observations.-From Jurassic times the branching Lithothamnia have played an important rôle in the formation of limestones, especially those associated with reef-making corals. The distinguishing characters of this plant, apart from the fruiting organs, are not easily defined, the form of the thallus being very variable. Solms Laubach ${ }^{1}$ cuts the gordian knot in that he says. "We shall do well to follow Unger in this matter, and put them all together as Lithothamnium ramosissimum."

My own conviction is, that when the cell structure is well preserved. and the mode of frutification shown, the fossil specimens are as good as living examples for diagnostic purposes. It has

[^0]hitherto been the usage amongst palaeobotanists ${ }^{1}$ to separate the encrusting forms of Lithothammion as Lithophyllum; but as Foslie (whose untimely death we have recently had to deplore), showed, ${ }^{2}$ that, having regard to the reproluctive organs of the plants, that method was based on insufficient ground. From a study of the recent forms of the group, Foslie included nearly all the species of Lithophyllum in Lithothamnion, the latter genus being defined by the downward growth of the conceptacles into the frond (subgen. Éulithothammion, sect. Imatae) or by their superficial character (sect. Evanidae). The present species falls into the first section of the subgenus mentioned.

The conceptacles with tetraspores can be found in the fossil examples hy slicing, almost as easily as in the recent forms. In these specimens from the polyzoal rock of the Mallee bores, it is found that the conceptacles are inmersed in the thallus, the surface of which is sometimes orerarched above the conceptacles. The conceptacles here examined were slightly broken during slicing, so that the true outline of the cavity was not seen. It has already been stated ${ }^{3}$ that the tetraspores "could be but imperfectly fossilised," since they contain very little carbonate of lime. It is, therefore, particularly interesting to note that the tetraspores are here present, and preserved as glanconite pseudomorphs of a pale green tint. The example figured shows two of the tetraspores clinging to the inner wall of one of the conceptacles, whilst another is seen in an adjoining cavity. These tetraspores are ovoid, and pointed at the base of attachment. The pseudomorphic change into glauconite shown by these fossil bodies is more easily understood when we compare them with the sarcode bodies of Foraminifera replaced by the same substance, for I am inclined to believe that the glauconitisation of foraminifera takes place as a reactionary product of the protoplasm, and not as a mere infilling of the dead shells, in which case we should most probably get a concentric structure developed in the grlauconite. This assumption can, of course, only be proved by detailed observation and chemical experiment.

In Lithothamnion $n n m m$ m!iticum ${ }^{\text {t }}$ the cell structure is quadrate and smaller than in I. ramosissimum, to which we refer nearly all the present examples. The specific standing of the latter is further

[^1]supported by the external form of the specimens, which is in general agreement with other Miocene examples, of which some of the synonymy is given above.

Rothpletz ${ }^{1}$ gives the cell measurement of his examples of $L$. ramosissimum as $20 \times 14-16 \mu$, whilst the specimens from the Hallee vary from about that proportion to $30 \times 17 \mu$. This amount of variation in the cell measurement can he found in a single branch in our specimens, so that the dimensional character must be taken with other factors, viz., the habit of the branches and the form and position on the thallus of the conceptacles, whether immersed, subimmersed, or prominent.

There is little doubt that the encrusting lavers of calcareous algae found on some of the pebbles in the present borings are merely the early stage of the above, or a closely allied species, as the cells agree in form, and spread out fan-wise over the surface as in the basal parts of a branching specimen.

The above species is a penuliarly Miocene form. It constitutes the bulk of the Leithakalk (Tortonian) of the Vienna Basin. In Eastern Asia it accompanies Miocene forms of Lepidocyclina, such as have been recorded from Japan, Timor, New Guinea, Amboina, Batu Island, Formosa and Riu Kiu.

Distribution.-Bore 3, 201-220 feet and 226 feet. Bore t. 16:3170 feet. Bore 5, 163-175 feet (figd.), and 175-189 feet. Bore 10 , 310-320 feet. Bore 11, 438-440 feet, and $457-458$ feet.
[In working out the above details I have been assisted with literature, and specimens of recent material, through the kindness of Mr. C. J. Gabriel.]

## Lithothmanion aff. Lichenoides, Ellis and Solander.

Millepora lichenoides, Ellis and Solander, I786, Nat. Hist. Zoophytes, p. 131, pl. xxiii.. fig. 9.
Lithothammion lichenoides, Ell. and Sol. sp., Fosslic. 1900. Kongl. Norske Vidensk. Selsk. Skr. (No. 5), p. 14, No. 55.

In this form the branches are flattened or fromdose, with the conceptacles superficial.

Distribution-Bore 11, 457-458 foet.

Lithothamion spp, indet.
Specimen a.-Bore No. 3, about 226 feet, vielded two pebbles partly formed of an encrusting Lithothammion.

Specimen b.-This is an encrusting thallus, very thin, one cell layer in thickness, spread over the surface of a phosphatic pehble from Bore 3, 206 feet. The elongate-rectangular cells are like thuse of Lithothamnion ramosissimmm, hut much larger. They spread far-wise over the surface, and the limiting plane of each sucressive growth is mudulate or convex. In some respects it is allied to Lithothammion lichenoides, Ellis and sol. sp., which Foslie places in his second section (Evanidae) of the subgenns Eulithothamnion. The question here arises whether a form like $I$. ramosissimnm, when attached to a rolling pebble, does not conform to its suroundings and show a varietal mutation on account of the abnormal comlitions of its existence.

## Genus LITHOPHYLLICM, Philippi.

## (?) Lithophydeum sp.

This is a comparatively large fragment, subcylindrical, measuring $11 \times 5.5 \mathrm{~mm}$. It cannot be referred to a branchlet of $L$. comossissimum, since the successive concentric layers of the growing thallus are separated by narrow spaces, which show it to be persistently encrusting ; and what is more important, there are circular depressions over the surface on the summits of low monticules, pointing to superficial conceptacles.

Bore 1, 212-215 feet.

## Animalia.

## FORAMINIFERA

## Fam. MHLOLIDAE.

Genus TRILLANA, Schhmberger.
Trillisa bowehini, schlumberger. (Plate XVI, Fig. 4).
Trillina howchimi, schlumberqer, 18933, Bull. Soc. (ieonl. France, ser. 3, vol. xxi., p. II9, woodent fig. 1, and pl. iii. fig. 6. Chapman, l908. Proc. Limm. Soe. Nıw South Wales, vol. xxxii., p. 753, pl. xxxix., figs. T-9.
Ohservations.-This remarkable and easily indentifiable spories was figured and described by M. Nehlumberger from the lower beds at Mudly Creek, near Hamilton, where the Rev. W: Howchin found it to be moderately common. It also ocours in Miocene strata in the New Hebrides. It was only occasionally found in the present bores, in strata identified as Janjukian by the general characters of its facies. It here evidently persists into a higher horizon than that
represented by the Muddy Creek lower beds (Balcombian), for it is associated in Bore 4 with some undoubted Kalimnan forms, as Bathyactis beaumariensis, although the remainder of the fauna at 163-170 feet is essentially Janjukian.

The example figured above resembles M. vulgaris in contour, whilst others are nearer M. tricarinata in outline, the species being much subject to variation.

Jistribution.-Bore 2, 211-240 feet, very common. Bore 3, about 260 feet. Bore 4, 163-170 feet. Bore 11, 267-270 feet.

## Genus ORBITOLITES.

Orbitolites conplanatus, Lamarck.
Orbitolites complamotms, Lamarek, 1801, Syst. Anim. sans Vert., p. 376. Carpenter, 1856, Phil. Trans., p. 224, pls. iv-ix.
Observations.-As a fossil this species has been previously recorded from Victoria by Mr. Howchin, as rare at Muddy Creek (lower beds; Balcombian) ; it has also occurred in the Govt. wellboring in the Murray Flats, South Australia. O. complanata, as remarked by Mr. Howchin, was living on the South Australian coast to within Pleistocene times. but is now extinct in that area.

Distribution.-In the present borings this species is of common occurrence, and seems mainly confined to the greensand and phosphatic deposits of the Janjukian and Kalimnan series.

## Fam. LITUOLIDAE.

Genus AMMODISCUS, Reuss.
Ammodiscus ovalis, sp. nov. (Plate XVli., Figs. are, b).
(?) Ammodiscus sp., Chapman and Howchin, 1905, Mem. Geol. Surv. New Kouth Wales, Palaeont. No. 4. Foram. Permo-Carh. Limestones of New South Wales, p. 11, pl. i., figs. 12a-c.
Description.-Test composed of fine arenaceous mud, consisting of a depressed, sparsely-coiled shell, elongated in one direction to form an irregnlar oval. Thimer in the centre than at the periphery.

Dimensions.-Longer diameter. . 692 mm ; shorter diameter, 384 mm . Thickness, cir., .077 mm .

Ohservations.-The examples doubtfully referred to the genus Ammodiscus by Mr. Howchin and myself, from the Carbopermian
of New South Wales, is of the same type of shell as the above, and may be regarded as a depauperated and sparsely coiled form of the Ammodiscus type. The nearest allied examples to the above are the Ammorliscus robertsoni, Brady sp., ${ }^{1}$ and A. auricula, Chapman. ${ }^{2}$

Distribution.-Bore 10. 160-186 feet.

## Fam. LAGENIDAE.

Genus FRONDICULARIA, Defrance.
Frondicularia lorifera, sp. nov. (Plate NVI., Fig. 6).
Description.-Test, compressed ovate, with pointed extremities, more acute at aboral end. Edges of test, blint. Chambers numerous, about fifteen. The surface of each acute $V$-shaped chamber thickened with redundant shell-growth, especially towards the oral area of each segment.

Dimensions.-Length of type specimen, + mm. ; greatest width, 1.615 mm . ; thickness, .3 mm .

Affinities.-In outline somewhat like the associated species of Frondicularia in these borings. viz., $F$. inaequalis. It is distinguished from that form, however, by the wide angle of divergence made by the two upper edges of each segment. and the exceptionally heavy shell with thick, strap-like layers of redundant growth on the lateral surfaces of the test.

Distribution.-Bore 4, 16:3-170 feet. Bore 11, 4.38-440) feet.

## Fam. ROTALIIDAE.

Gemus CARPENTERIA. Gray.
Carpenterla protelformis, Goés. (Plate XVI., Fig. i).
Carpenteria halaniformis, Gray, var. proteiformis, Goës, 1882, K. Svenska Vet.-Akall. Handl., vol. xix., No. 4. p. 94, pl. vi., figs. 208-214; pl. vii., figs. 215-219.

Otsertations.-This species is found both in the Balcombian and Janjukian faunas; in the former at Muddy Creek (lower beds), and in the latter at Batesford.

[^2]The specimens from the polyzoal rock of the Mallee borings are invariably arrested in growth, showing only the first tier of segments above the primordial group.

Distribution.-Bure 11, 540-542 feet ; 544-546 feet; 560-562 feet.

Gemus PIthyINULINA. Parker and Jones.
Pulfinclina scabbicula, Chapman.
Pedvimutime scabricular; (hapman, 1910, Proc. Roy. soce
Vict., vol. xxii. (N.S.), pt. ii., p. 288, pl. ii., figs. 2a, b.
Observations.-This distinct little species was hitherto known only from the Batesford limestone. It is here moderately common, and restricted to the polyzoal rock of the Mallee bores.

Distribution.—Bore 11, 54(0-542 feet ; 554-556 feet.
Pulundelna calabra, Custia sp. (Plate XVI., Figs. 8a, b).
Rosalina calabira. C'osta, 1856, Pal. del Regno di Napoli, pt. ii., pl. xiv., figs. 6a-c.
R. thiura, Stache, 1864, Novara Exped., Geol. Theil, vol. i.. p. 279 , pl. xxiv., figs. $29 a-c, 30 a-c$.

Observations.-This remarkable and distinct species was fiymed hy O. G. Costa from the Italian Tertiaries, but not dexcribed. There is no doubt about its identity with onr Mallee bore specimen.

The Rosalina thiara of Stache is synonymous with Costa's species. It was described from the Tertiary marl of Whaingaroa Harbour, N.Z., which yields a microzoal fanna closely resembling that of the deeper parts of the Mallee bores.

The test of our specimen is slightly rough, and is in the form of a depressed nautiloid spiral, flatter on the superior face. which shows a many-chamberel, short, segmented whorl with constricted sutures, closely and densely coiled on the central axis. Winderside somewhat concave, showing the outer whorl. Septal face where fractured shows the shell-wall to be thick.

Dimensions.-Diameter of test. 3.84 mm . ; thickness, 1.25 m m m .
Distribution.-Bore 5, 163-175 feet.

## Genus GYPSINA, Carter.

Gypsina howchini, Chapman.
Gypsima houchini, Chapmath, 1910, Proc. R. Soc. Viet., vol. xxii. (N.S.), pt. ii.. p. 291, pl. ii., figs. $4 a, b ., \mathrm{pl}$. iii., figs. 3-5.
()hserrations.-This species was hitherto only known from the Batesforl Limestone. Typical specimens were found in the present bores as follows :-

Bore 3, 226 feet. Bore 5, 162-163 feet. Bore 11, 440-442 feet.

## Fam. NUMMULINIDAE.

Genus POLYSTOMELLA, Lamarck.
Polystomella striatopunctata, F. v. M. sp, var. evoluta, nov. (Plate XVI., Fig. 9).

Description.-This variety is very distinct from the type-form in having the earlier whorls exposed on the umbilical area. Thelatter is depressed and wide, compared with that of the specific form. The retral processes in this varicty are strongly developed, and the interspaces, especially on the last whorl, are circular and deep towards the inner lomudary of the whorl.

Diameter of test in figured sperinen, 466 mm .
Olservations.-Typical examples of the species itself are also formd in these bores; as, for instance. in Bore 11, 170-175 feet, and in the later deposits, but more sparingly than the variety abovedeseribed.

An evolute variety of the above species has lately been described by Messrs. Heron-Allen aud Earland, from Selsey and Bognor in Sussex. under the varietal name of selsegensis. ${ }^{1}$ That variety was recorded as " both recent and fossil" (probably pleistocene). It differs from the present evolute varicty in having an encrustation of redundant shell-growth over the umbilicus, which is, moreover. not so wide nor so deep as in our variety.

IDistribution.-Bore 9. 26:3-27.3 feet. Bore 10, 160-186 feet: 195-225 feet ; 296-306 feet.

## Genus OPERCULINA. d'Orbigny.

Operculina vevosa, Fichtel and Moll sp.
 pl. viii., figs. $e-h$.
Amphistegina comingii, Carpenter. 1859. Phil. Trans.. p. 32, pl. v., figs. 13-17.

Jommalites cumingii. Carp.. H. B. Brady, 1884. Rep. Chall., vol. ix.. p. T49, pl. exii.. figs. 11-13, woodent. fig. 22.

[^3]İummulina venosa, F. and II. sp., ('hapman. 1895. Proc. Zool. Soc. Lond., p. 47.
Observations.-This interesting species occurs twice in these bores. It was accepted as a nummulite by Dr. H. B. Brady in his work on the "Challenger" foraminifera (loc. supra cit.), but he did not seem quite convinced that it belonged to that genus, for he says, ${ }^{1}$ " On the whole I am inclined to agree in this latter determination " [as a nummulite by Carpenter] " notwithstanding the fact that in any large collection of specimens there are invariably a certain number in which the segments of the final convolution spread out radially, so as to impart an Operculina-like aspect to the shell."

In my own cabinet there is a series of tests of this form from the East Indian Archipelago, which shows extreme modification, ending with the typical Operculina.

Operculina venosa is found on parts of the Australian coast at the present day, in the neighbourhood of the Great Barrier Reef.

Distribution.-Bore 1, 215-244 feet. Bore 11, 566-568 feet.

## SPONGIAE. <br> CALCISPONGIAE.

## Sipicules, indet.

The spicules of calcareous sponges enumerated in the lists of fossils from the borings are all of the tri-radiate type, and conform to figures 4,5 and 6 of plate iii. in Dr. Hinde's description of Plectroninia halli in their outline, but are more than twice the size. ${ }^{2}$ No precise identification is, however, attempted here.

## ANTHOZOA.

## HEXACORALLA

## Fam. TURBINOLIIDAE.

Holcotrochus crenulatus, Demant. (Plate XVII., Fig. 10.)
Holcotrochus cremulatus, Demant, 190t, Trans. R. Soc. S: Austr., vol. xxviii., p. 3. pl. ii., figs. $4 a-c$.
Ohservations.-This neat little coral is not easily confused with the only other known form of the genus, $I I$. scriptus, for the latter differs in its more broadly-ovate transverse section, and in the horozontal scribing of the costae; whilst the surface of the thecal wall in $H$. crenulatus is gramulate.
2. Quart. Journ. (ieol. Soc., vol. Ivi. 19.40 , pp. 50.69 , plts. iii.-v.

This is the first recorded occurrence of $I /$. crenulatus as a fossil. Except for a slight weathering of the external surface, the two specimens found here are in every way comparable with the recent examples in the Dennant collection, from South Australia. These were obtained by Dr. Verco at Cape Borda (15 fms.) ; St. Vincent's Gulf ; and Backstairs Passage ( 22 fms.).

The related $I /$. scriptus, also found recently in Backstairs Passage, S.A., at 22 fathoms, was originally described by Mr. Deunant from the Tertiary of Muddy Creek, and supposed by that author to come from the lower beds. The pink. ferruginous appearance of the type specimen now in the National Museum collection suggests, however, that it came from the red limestone between the Balcombian and the Kalimnan series at Muldy Creek, and ahont which there is now evidence for believing it to be of Janjukian age. The rolled examples of $H$. scriptus found by Dr. T. S. Hall. came from the Kalimnan of Forsyth's Grange Burn. Hamilton.

Distribution.-H. cremulatus necurs in Bore 11 of this present series at 197-199 feet, associated with Kalimman fossils.

## OCTOCORALLA.

PSEUDANONIA.
Fam. ISIDAE.
Genus MOPSEA. Lamaroux.
Mopsea tenisoni, sp. nov. (Plate ČYfl., Figs. 11a, $b, 12 a, b$, 13 and $15 a-c$; Pl. XIX., Fig. 39).

Isis sp., Tenison Woods, 1862. (ieol. Ohservations ius. Australia, plate facing, p. 73, fig. 6.
(?) Isis dactyla, Id., palaeont, New Zealand, pt. iv.. 1880, p. $7, \mathrm{pl}$. i., fig. 1.
ef. 1sis sp., Duncan, 1875, Quart. Journ. Feol. Soc.. rol. xxxi.. p. 674, pl. xxxviiiA, figs. 1-4.

Isis sp.. Id., 1875, ibid.. p. 675. pl. xxxviib., fig. 4.
Preliminary Note.-Tenison Woods in 1880 figured and described some fossil remains possibly identical with the above species under the name of lsis dactyla, from Hutchinson's Quarry, Oamaru. but they were so badly preserved as to preclude an exact comparison. It seems better, therefore, to give a distinctive name. in honour of $T$. Woods, who actually figured this form in 1862 from the Mt. Gambier deposits. In his description of the fossils. he states, amongst other points, that "The condyles are convex or sub-conical, concentrically
striate," but he does not mention the radial striae seen in our form. Judging from an examination of several hundred examples of the calcareous internodal joints of Mopsea from the Mallee bores, Tenison Woods' specimens may have been abraded, so that the fine, salient radii were cleared away, leaving only the more deeplymarked concentric growth stages of the calcareous part of the axis. Specimens in the present collection show both conditions.

Description.- C'alcareons joints forming the internodes, circular to elliptical in transverse section; short and wide when from the base of the coral; longer, to extremely slender and circular in section where forming the middle and distal joints. Sides straight to incurved, and slightly dilated at the ends, especially in the terminal joints; with numeroms, fine linear ridges or striae. Articular facets flat to conical, with strong concentric rings of growth and numerous fine radii. The concentric rings are undulate, and outwardly concave to meet the axial radii at the cusps. The radii are in systems of eight, and these, with the concentric lines, produce a very ornate effect on the articular surface in well meserved specimens. The striae of the crlinder correspond with the radial lines of the condyles.

Microscopic Structure of the Calcareous Internodes.-A transverse section of the joints shows that the axis is built on a system of eight rays which send off secondary and tertiary branches; and these consist of thin caleareous plates with a slight upward curvature, giving a tegulate appearance to the rays, in section. The inter-radial areas appear to be formed of fused, spicular bodies. Compared with the structure of the ealcareous axis in a living Mopsea (1. cf. encrinula, Lamarek sp.), the fossil species here described (1. tenisoni) shows fundamentally similar structure, though on a coarser scale. This is probably owing to the rays not having advanced beyond the primitive eight. The tegulate appearance is seen in both the living and fossil species.

Dimensions of Calcareons Joints.-Three trpical specimens were selected.
1.--Specimen of a hasal joint; $9 \times 8 \mathrm{~mm}$. in diameter. 4 mm . high.
B.-A median joint, that is, from the middle bramehes of the corallum; 2.5 mm . in diameter, 5 mm . high.
( ${ }^{\prime}$. A terminal joint; .75 mm . in diameter, 2.25 mm . high.
Jistribution.-Bore 1, 215-24t feet. Bore 3, 201-220 feet; 226 feet. Bore 4, 163-170 fect. Bore 8, 210-21! feet. Bore 9, 315-325 feet. Bure 10, 310-320 feet. Bore 11, 267-590 feet.

Spirnles Associnted in the Deposits with Mopsea.-Alcyonarian spicules are not uncommon in the finest washings of the polyzoal rock of the Mallee bores. They appear to he all of one general type, and without much douht may be referred to the same organisms as these here deseribed. They agree with certain species of Mopsea found round the Anstralian coast at the present day, and closely resemble those figured under the name of Mopsea whiteleggei by Thomson and Mackinnon. ${ }^{1}$ a delicate and graceful plume-like form from Broken Bay, New South Wales. The fossil spicules here recorded are fusiform, twisted to a long S-shape, or V-shape, and sparsely covered with short rounded, blunt or square-ended tubercles. They measure from . 375 to .4 mm . in lengtl.

Mopsea hamletoni, Thomson sp. (Plate XVII., Fig. 16).
Lsis sp., Duncan, 1875, Quart. Journ. Geol. Soc., vol. xxxi., p. 674. pl. xxxviii.a, figs. 5 and (?) 6, 7, $7 a$.
/sis sp., 1, Id., 1880. Palaeontologia Indica (Sind Fossil Corals and Alc̣onaria) ser. xiv., vol. i., pt. 1, p. 109, pl. xxviii., figs. 8, 9.
lsis hamiltomi, Thomson. 1908, Trans. and Proc. N.Z. Inst., for 1907, rol. xl., p. 99, pl. xiv.. fig. 1.
Mopsea hamiltoni, Thomson sp., Chapman, 1912, Mem. Nat. Mus., Melbourne, No. 4, p. 43, pl. vi., figs. $3 a, b: 4$.
Observations. - The calcarents joints of this species are searce in the present collection, as compared with those of the foregoing Mopsen tenisoni. Their differential characters are well defined in most cxamples, as seen in specimens now figured, in which the radial lines on the condyles are very pronounced and distinctly crenulate.

Duncan's Indian specimens referred to above were from theGáj Keries (Burdigalian); Naigh-Nai Valley, S.W. of Schwan. Duncan compares these fossils with his previously figured examples from C. Otway, Victoria; and there is no doubt of their close relationship if not identity.

Mopsea hamiloni is now known from the C'ape Otway Series. from King Island, and from the greensands of Kakami. New Zealand, as well as from three of the borings in the Mallee; whilst a practically identical form occurs in the fáj Series of India.

Distribution.-Bore 3. 226 feet. Bore 4. 163-170 feet. Bore 11. 342-510 feet.

[^4]Genus ISIS, Linnaeus.
Isis compressa, Duncam. (Plate XVII., Figs. $17 a, b ;$ Pi. NiN., Fig. 41).

Isis compressa, Duncan, 1880, Palaeon tologia Indica (Sind Fossil Corals and Alcyonaria), ser. xiv., vol. i., pt. I, p. 109, pl. xxviii., figs. 4, 5.

Observations.--Two fragments of the stony axis of the alcyonarian occur in the Nallee bores, which are comparable to the above form. The largest fragment measures 12 mm . in length, and its greatest transverse diameters are $6.25 \times 4 \mathrm{~mm}$. In shape it is a flattened cylinder, and is superficially grooved with coarse longitudinal striae. The fractured surface of one of the fragments is, in the central area, discoloured to a bluish black, as if by residual organic staining. The articular surface is nearly flat, and has all the characters of Duncan's figured specimen.

A transverse section of this fossil under the microscope shows it to consist of undulose concentric laminae, with a sub-circular central portion having numerous short radial extensions; and these layers, by accelerated growth along one axis, cause the stem to finally assume an elliptical outline. The cusps of the concentric layers form the costae on the external surface of the calcareous axis.

Dunean's specimens were from the Gáj beds of Tandra Ráhim Khán.

Occurrence.-Bore 3, 226 feet. Bore 11, 495-500 feet.

## NOTE ON THE (EENERIC AFFINITIEA OF THE ABOLE ALC'YONARIAN FOSSLIAK

Galcareous joints of Alcyonarians have long been known from the Tertiary beds of Southern Australia and New Zealand. These fossils have hitherto been referred to $I$ sis. Tenison Woods in 1862 figured a basal joint from the Mount Gambier limestones which he referred to that genus. ${ }^{1}$ Subsequently Duncan provisionally referred to 1 sis and Mopsea the collection of alcyonarian remains sent to him from Australia (Cape Otway beds), accordingly as the calcareous joints are branched or mbranched. ${ }^{2}$ That is to say, if branched, they belong to lsis, if not they may helong to Mopsea. or are unbranched joints of /sis. This view now appars to be erroneous, for in Mopsea encrinula branching invariably takes
2. Gllart. J. (ienl. Soc'., vol. Ixxi., p. 673.
place on the calcareons internobles. ${ }^{1}$ The spicules (scleroblermites) of Mopsea are stated to be club-shaped, ${ }^{2}$ but the majority of those figured in the "Challenger" report and from the "Thet is" expedition are spindle-shaped, though sometines approaching the clavate type.

In Melifordes the internorles are calcareous with a horny matrix. In the present examples referred to Mopsen, the microscopic structure of the joints excludes that genus from consideration, since they are seen to be solidly and originally calcified.

There is, however, at least one species in the present collection which agrees with Isis, as seen in the long, and coarsely-grooved joints, and the dense lamellated structure of the axis.

## CRINOIDEA.

## Fam. COMATULIDAE.

Gemus ANTEDON, de Fréminville.
Antedon protomacronema, sp. nov. (Plate XVII.. Figs. 18 ¿a, b).
Description.-Isolated centrodorsal nearly hemispherical seen from the side; with more than 30 cirrus sockets, arranged in threes and fours vertically, alternate; borders of sockets prominent, with indications of a crenulated surface to the rim. Ventral aspect subcircular, showing the $g_{r}$ roores of the radial pentagon, which increase in width near the periphery. Dorsal aspect subpentagonal at base. with a central depression apparently not perforate or permanently open.

Dimensions.-Type: Height of centrodorsal. 1.154 mm ; width ventrally, 1.7 mm .

Observations.-Another specimen, probably of this species, and twice the dimensions, occurs in the same sample, viz., Bore 11, 430-432 feet. It is, however, not so well preserved, and consequently is not figured.

Separate brachial ossicles, which may be referable to this or an allied species, are common in the Mallee borings, in the Janjukian series, having a Mount Gambier facies; and also at Batesford, Greelong. ${ }^{3}$

There is still another species of Antedon in the southern Australian Tertiaries, which is found at Torquay. Victoria, and at Mount Gambier. This will be described later, from specimens in the

[^5]National Museum. It is a comparatively large form, with few cirrus sockets and a low centrodorsal.

Affinities.-One of the nearest allied forms to the above species appears to he Autedon macromema, Miller sp., ${ }^{1}$ a Feather-star which has been recorded by the "Challenger" from Port Jackson at $30-35$ fathoms; and is also found in King George's Sound and Port Stephens.

Occurrence.-Centrodorsals (2 examples). Bore 11, 430-432 feet. Brachials (probably of this species). Bore 3, 226 feet. Bore 4, 163-170 feet. Bore 11, 430-432 feet; 438-440 feet; 440-442 feet; $442-446$ feet; 446-44~ feet; 457-458 feet; 540-542 feet; 546-548 feet; 558-560 feet ; 560-562 feet; 562-564 feet.

Antedon, sp. (Plate XVili., Fig. 19).
Observations.-A cirrus joint of a larger species than that described above as A. protomacromema occurs in the polyzoal limestoneof the Mallee. It may be referable to the Mount Gambier and Torquay species before noticed.

Occurrence.-Bore 11, 560-562 feet.

## ASTEROIDEA.

## PHANEROZONIA.

## Genus PENTAGONASTER, Linck.

Pentagonaster sp. (Plate XVili, Figs. 20, 21).
Observations.-Marginal plates of a large species of Shield-star have already been recorded by Dr. T. S. Hall ${ }^{2}$ from the Lower and Upper beds of Muddy Creek; and alsu from Spring Creek, Waurn Ponds and Batesford.

In the Mallee borings the genns Pentayonaster is well distributed through the polyzoal rock series, and represented both by subtriangular plates from the margin, and subpolygonal to rounded plates of the abactinal area. A few of the plates met with are covered with minute tubereles, as in those of the common living Pentagonaster aurata.

Occurrence.-Bore :3, 226 feet. Bore 11, 197-590 feet.
2. See I'. H. Carpenter. Report on the ('omatulae, ('hall. Rep. Zool., vol. xxvi., pt. Ix., lss8, 1. 212.
2. Proc. loy, Soc., Victoria, vol. xv. (N.S.), pt. i., $19 \mathrm{~m}_{2}, \mathrm{p}$. 81, pl. xi., figs. 4, 5.

ECHINOIDEA.

CID.AROID. 1
Fam. (ID)ARID.IE.
Gems GONIOClDARIS, Desor.
(Govolcharas sp. (Plate XVIl, Fig. 2. 2) .
Olservations.-Amongst other cidaroid spines occurring here there is a small spine differing from those of the living $G$. tubarin, Lanl. sp. ${ }^{1}$ in having the shaft hour-glass shaped, smooth, with blunt apical tubercles; whereas those in $G$. turbaria are always more or less Hattened, and tubercular along the shaft, excepting in the case of the secondary spines, which are longitudinally serially gramulate. From Leiocidaris it differs in the clavate form of the spine.
(ioniocidaris (misprinted " Gomocidaris") is recorded byy Tate in his "Census of the Older Tertiary Fauna of Australia.' 2

Dimensions.-Length. 8 mm . ; greatest width at abont one-third from the base, 3.1 mm .

Occurrence.-Bore 11, 5.30-5.55 feet.

## CLJPEASTROIDA.

## Fam. FIBULARIIDAE.

## Genus ECHINOCYAMITs, van Phels.

Subgeuns SCUTELLINA, Agassiz.
Echinocyamus (Scuteldina) patella, Tate sp. (Plate XVIII., Fig. 23).

Ohservations.-In 1907 Dr . T. S. Hall ${ }^{3}$ described a sicutellinn tentatively referred to the abore species, having a definite marsupium or brood pouch. This structure was new for this order of echinoids. the Clypeastroida. 4 The figurel example came from the polyzoal rock near the mouth of the Glenelg River, Victoria, and Dr. Hall also reconded other specimens obtained by him from Mount Ciambier in a similar rock. Amongst the score or two tests of the above species in the Mallee bores collection one very fine example with a broud ponch

[^6]occurs. In outline it is of an elongate or ovate type, but comes within the limit of variation in the ambital ontline assmmed by this species. This example measures \&.5 mm. $\times 7$ mm.. and was found in Bore 11 at $.000-50$ feet in white polyzoal rock of the Mount Gambier trpe.

In one instance (Bore $8,165-180$ feet) an example of this species was found with the periproct inframarginal, but this need not be considered as more than an exceptional character, as such variation is characteristic of the genus as a whole, but not of the species moder present notice.

## ANNELIDA.

## POLYCHAETA TUBICOLA.

Fam. SERPULIDAE.
(ienus SERPULA, Limé.
(Sbrplla ousbexsis, sp). now. (Plate NVili, Figs. 24, 25 ;
Pl. NIX., Fig. 42).
Description.-Tube free, stout, liexagonal in section, gently tapering and slightly corved ; the cusps formed by the six longitudinal irregular ridges. Exterior of shell amulated by variably spaced rings of growth, prodncing a roughened appearance on the edges of the ridges. Interior of tube round and polished.

Dimensions.-Figured specimens (co-types). Spec. A.-Length. 5 mm. ; width, 2 mm. Spee. B.-Lengtlı, 6.5 mm. ; greatest width, 1.75 mm .

Olsermations.-Several foms of wom thises ascribed to Serpula approach the present species, bat none seems to exactly match it in its hexagonal and Huted eross section. The specimens are very constant in character. From the shells of Dentalium they are typical shell-structure under the microseope (pl. xix., fig. 42).

Ocemrence.-Bore :3, 210 feet. Bore 11, .562-590 feet. Fairly common.

## Genus DITRITA, Berkler:

Ditrupa cornea, Limé sp., var. wormbemensis, Mectoy: (Plate XVIII., Figs. 26-28).

Ditrupe mormbetiensis, MeCoy, 1sity. Prog. Rep. (icol. Surv. Vict., pt. 1. p. 22, fig. f. Chapman, 190.). Vict. Nat.. vol. xxi., No. 12, p. 180.
Description.-Tube rather small, slender and tapering; swollen near the apex and trumated from the shomlder of the swelling to
the oritice, the edge of which is thin and sharp. Surface smooth. but for indistinct rings of growth. Occasionally these rings are rery thick, and resemble collars ${ }^{1}$ Lengths of two typical examples. \& mm, and ! ! 5 mun., respectively ; breadths, 1.5 mm, and 1.5 mm, at the apical emul.

Ohsermations. -The type species has heen described under many Hanes. ${ }^{2}$ As a fossil it ranges in Europe from the Diddle Eocene to the Pleistocente. and is also found living.

The prescht variety is more regularly tapering than Brocehi's "Drutalinm" coarctatum. ${ }^{3}$ It is closer to Sowerby's "Dentalitum" incrossatum, ${ }^{4}$ from which it differs in its more irregnar surface ant gemerally smaller size. The latter species is syomymous with Ditrupar eorner.

The original specimen refersed to low Moy, from the Janjukian ironstone of stamell. Victoria, is merely a mould, and the figure given in the Progress hepont (loce. supra cit.) hardly coincides with a squeeze which I have taken from the type specimen, and now figured (see pl. xviii., fig. 26). Since Mafor comnects this specimen with those from Wormbete Creek, Barwom Valley, there leaves no romm tor doubt as to its identity. This variety is. so far as known, quite restricted to the Janjukian series in Victoria.

Ocenrence.—Bore :3, 211-220 feet; 226 feet. Bore 4, 16:3-170 feet: 180-190 feet. Bore 5, 163-175 fect; 175-189 feet; 189-190 feet. Bore $6,150-154$ feet; $158-161$ feet. Bore 9, 315-325 feet. Bore $10,254-296$ fect : $310-320$ feet. Bore $11,272-315$ feet ; 331342 feet ; $342-3+9$ feet ; $353-370$ feet; $448-4.50$ feet.

Ditripa, cornel, L. sp, var. constracta, var, nov: (Plate XVIIf. Figs. 29, 30).
Itescription.-Tube lapering. only slightly eurved, broken up into mondesties by constrictions at intervals along the tube. The nowlose swellings are generally fomed at or towards the apical end, thos showing the rarietal chatacter to be partly attributable to senility. Tube larger and stonter than in Var.urombetiensis.

Oermrence-Bore 1. 215-244 feet. Bore 3, 226 feet. Bore 4. 16:3-170 fect: $1 \times 0-190$ feet. Bore 5. 16:3-175 feet. Bore 10 , 310320 feet.

[^7]Genus SPIRORBIS, Lamarek.
Spirorbis heliciformis, Eichwald. (Plate XTllt., Fig. 31).
Spirorbis heliciformis, Eichwald, 1853, Lethaea Rossica, vol. iii., p. 52, pl. iii., fig. 11. Rovereto, 1904, Pal. Ital., vol. x., p. 59.
Observations.-Several speeimens, agreeing in all details of shape and ornament, were found in the present series. Some of them are attached to the interior of bivalved shells.

A similarly ornamented (?) s'pirorhis, but of much larger dimensions, is figured by Goldfuss ${ }^{1}$ from the Oolite and Lias of Germany, under the name of Serpula convoluta. Eichwald's species came from the Tertiary (probably Miocene) of several Russian localities. as Zukowie, Zalisce and the districts of Volhynia and Porlolia. Rovereto found this species in the Miocene of Ritzing and Neulerchenfeld in Austria.

The fossil recorded as Spirorhis sp. from the polyzoal rock (Janjukian) of Seal River, King Island ${ }^{2}$ evidently belongs to the above species.

Occurrence.-Bore 8, 160-165 feet. Bore 11, 564-566 feet.

## Class POLYZOA.

Suborder CHEILOSTOMATA.
Fam. CATENICELLIDAE.
Genus CLAVIPORELLA, MatGillivray.
Claylporella sp. (Plate XVII., Fig. 32).
Observations.-A zoneimm of Claviporella was picked out of the material from Bore 5 at 163-175 feet, in the present series. The specimen is important from the fact that it corresponds with the peculiar little iron-stained bodies oceasionally found in the Janjukian calcareous sands of Wamrn Ponds, and which have heen referred to the foraminifer, Astrorhiza antulosa. ${ }^{3}$

## Fam. MEMBRANIPORIDAE. <br> Genus SELENARIA, Busk.

selenara mabgenta, Temisom Woods, var. spleabs, var. now.
(Plate X V $111 .$, Fig. 33).
Description.-The type species, $i$. marginata, is very common throughout the strata in the bores referable to the Kialimnan amb

[^8]Janjukian series. Some of the forms, however. nearest the little variety lucens, Macfillivay, ${ }^{1}$ with the polished dorsal surface have a distinct spiral arrangement of the zooecia viewed from the lower or ventral aspect of the zoarimm. Another feature invariably acennpanying this varietal character, and which is sometimes met with in other species of the genus, is the inclusion of a little glanconite pebble in the eentre of the zoarium on its lower side. This probably formed a point of attachment for the initial zooecium.

Dimensions of figured specimen (type) : 1.87 mm . in diameter.
Occurrence.-Found in strata referable to the base of the Kalimnan and the top of the Janjukian.

Bore 5, 155-159 feet. Bore 8, 165-180 feet; 180-199 feet ; 210219 feet. Bore 9, 254-256 feet; 263-273 feet; 315-325 feet. Bore $10,230-254$ feet ; 254-296 feet. Bore 11, 199-209 fret.
'Fam. LEPRALHDAE.
Genus LEPRALIA, Johnston.
Lepralla gippslandi, Waters. (Plate NIX., Fig. 43).
Lepralia gippslandii, Waters, 1882, Quart. Journ. Geol. Soc., vol. xxxviii., p. 509. MacGillivray, 1895. Trans. li. soce. Vict., vol. iv., p. 77, pl. x.. fig 21.

Observations.-Four typical examples of this species were found in a sample from Bore 5 , at $175-189$ feet. They form an encrusting layer upon a species of C'elleporo.

The speeies appears to have been hitherto confined to the locality of Bairnsdale.

Fam. SMITTHDAE.
Genus PORINA, d'Orbigny.
Porina gractlis, Il. Edwades sp.
Porine gracilis. M. Edwards sp., MacGillivray, 1885. Trans. R. Soc. Vict., vol. iv., p. 103, pl. xiv., figs. 21-24.

Observations. - The usual form of the zoarium in these deposits (polyzoal rock) is the lobed, bilaminate variation. In connection with this it is interesting to note that MacGillivray (loc. supra cit.) says. "The lobate form is that usually found recent, while the great majority of the fossil specimens are cylinhrical."

[^9]
## C'lass Blidr'HIOPODA.

## Fam. TEREBRATILIDAE.

Genus TEREBRATCLINA, d'Orbigny

Jescription.-Shell small, elongate orate, with tapering beak. Both valves convex, the pedicle valve deeper than the brachial; the latter depressed towards the anterior margin. Beak stout, prominent, with large foramen.

Whell surface ornamented with about 12 strong, ridge-like enstae, bifurcated at or near the anterior margin, and beset with squamose seales; costae becoming spinose at lateral margins of shell. Intercostal spaces fleep. Concentric lines of growth inconspicuous.

Jimrnsions.-Length, 4.75 mm . ; greatest width, 3 mm . thickness. 2 mm .

Ofserations.-This species is well represented in the Dennant collection by specimens from Flinders, from the Mitchell River, and from the Muddy Creek older beds.
T. Aindersi differs from T. trian!mlaris. Tate. ${ }^{1}$ in its more elongate shape and ovate ontline, and in the comvexity of the brachial valve.

Ocfurrencr-Twn specimens (one of which is the selected holotype), found in Bore 10. 310-320 feet.

## Fam. TEREBRATELLIDAE.

 Genus TEREBRITELLA, d'Orbigny
7escription.-Shell small, subeircular, compressed, with a prominent heak. Perlicle valve convex in the mombolal area. with slightly concave shomblers, flattened posteriorly. Brachial valve more depressed and only slightly convex in the posterion region. Surface nearly smonth, but under a low power seen to be finely, radially striate.

Jimensions.-Lengeth. 2.2:3 mm.; headth. $1.8 t$ mm. : thickness. 7.) min.

Ohserations.-This species bears some resemblance to the evenly (ontomed variations of $T^{\prime}$. moodsi, 'Tate, ${ }^{2}$ Jut is casily separated by

[^10]the prominent leak and the absence of a mesial fold on the brachial valve.
()cemarare-Bore 11. 430-4.32 feet.

Tembratelay porthanimed, sp. now. (Plate XVIll., Figs. 3fice, 37, 3ふ).

Deseription.- Shell small. rombly oval; outline subangulate. Valves plano-convex. Beak small, pointerl. foranen conspicuons: surface of pedicle ralve strongly arched dowsally; brachial valve with a shallow, broad simus, not extensive, turned down to meer the arched fold of the pedicle valve. Shell surface fincly punctate. and showing a few faint concentric lines tending to become laminate.
 thickness. 2.2.) mm.

Ohisrratinns.-This interesting little Terchratella is not infrequent in the bores. but never abundant. In only two cases were perfect cxamples secmred, on account of the liability of the valves to easily separate. By its well-developed median septum it is seen to be a typical member of this genns. The above species is of the Termbatella roodsi type. ${ }^{1}$ but that shell is much heavier. having a larger for:men and comparatively gigantic beak, and with a deeper and more ennvex brachial valve. At first sight $T$. portlandion might be comfused with Tate's Magasella lmata. ${ }^{2}$ which also occurs in these bores. but may be distinguished by the latter having a typical acute beak with smaller foramen, characteristic of that genus, and a rounder outline to the shell.

In the Dennant collection there is a typical example of the above species from Portland. which was doubtfully referred to Terebratella wordsi. and in the same tube are mumerous shells of a similar form from Beaumaris. My attention was first directed to this particular species some years ago in the National Museun collection, when sorting arer material from the white polyonal limestone of Portland. at which locality it is a typical fossil.
 27.3 feet. Bore 10, 254-296 feet; 310-320 fect. Bore 11 , 505-510 feet ; 515-520 feet ; 525-5.50 feet: 545-550 feet.

[^11]Genus MAGASELLA, Dall.
Magasella lunata, Tate.
Magasella lumata, Tate, 1899. Trans. R. Soc. E. Austr., vol. xxiii., p. 256, pl. viii.. figs. 3, 3'm.
It is interesting to note the occurence of this rare form in the present series, especially as it was previonsly found in some South Australian bores, viz., (roydon Bore, near Adelaide, at 400 to 1230 feet, and Murgurdawa Bore, near Wellington, at 213 feet. Tate also records the species from Belmont, near Geelong, and from the Murray River (Cliffs at Mannum.

Occurrence.-Bore 9. 315-325) feet: 11, 560-565 feet.
